jbird@birdaisolutions.com

ABSTRACT

Gene regulatory network analysis is essential for understanding disease mechanisms, identifying biomarkers, and prioritizing therapeutic targets. However, traditional workflows require labor-intensive manual effort across multiple databases with limited scalability. We present RegNetAgents, an LLM-powered multi-agent framework that automates gene regulatory analysis through intelligent workflow orchestration. The system integrates network modeling, network-based target ranking, pathway enrichment, and multi-domain interpretation into a conversational interface accessible via Claude Desktop without programming expertise.

Built on ARACNe networks from 500,000+ single cells across 10 cell types, the framework deploys four specialized agents executing in parallel with rule-based fallback for reliability. Automated therapeutic target prioritization ranks candidate targets using network centrality metrics (PageRank, degree centrality).

In a demonstration study of five colorectal cancer genes (MYC, CTNNB1, CCND1, TP53, KRAS), the framework characterized distinct regulatory architectures (hub regulators vs. heavily regulated genes) that align with known biological roles. Therapeutic target prioritization identified literature-supported TP53 interactors (WWTR1, YAP1, CHD4) among the top-ranked network neighbors based on topology. Additional high-ranking regulators (RBPMS, PRRX2, THRA, IKZF2) represent novel hypotheses prioritized for experimental validation.

Complete analysis of 99 regulators across 5 genes completed in 15-62 seconds, representing orders of magnitude speedup over manual workflows. This demonstration on a limited five-gene panel establishes proof-of-concept for the framework's ability to recapitulate literature-confirmed patterns and generate testable hypotheses. RegNetAgents is designed as a hypothesis generation tool to prioritize candidates for experimental validation, not as a replacement for wet-lab experimentation. The framework transforms labor-intensive analysis into second-scale automated hypothesis generation accessible to experimental biologists.

Keywords: gene regulatory networks, single-cell RNA-seq, multi-agent systems, workflow orchestration, biomarker discovery, therapeutic target identification, network centrality, PageRank, LangGraph, Model Context Protocol

INTRODUCTION

Background

Gene regulatory networks (GRNs) represent the complex interactions between transcription factors and their target genes, forming the fundamental control systems that determine cellular identity, function, and disease states (1,2). Understanding these networks is critical for identifying disease biomarkers, elucidating disease mechanisms, and discovering therapeutic targets (3,4). Single-cell RNA sequencing (scRNA-seq) technologies have enabled reconstruction of cell-type-specific regulatory networks at unprecedented resolution, revealing how regulatory architecture varies across tissues and cell types (5,6).

Traditional gene regulatory analysis requires researchers to manually query multiple databases and tools: network databases such as STRING (7) and BioGRID (8) for interaction data, pathway

enrichment tools such as Enrichr (9) and DAVID (10) for functional annotation, and extensive literature curation for domain-specific context. This fragmented workflow presents several critical limitations. First, the process is labor-intensive and time-consuming, requiring researchers to navigate different web interfaces, export data, and manually integrate findings across domains for each gene analyzed. Second, sequential processing limits scalability—analyzing multiple genes or comparing across cell types requires repeating the entire workflow. Third, domain expertise remains siloed, with cancer relevance, drug development potential, clinical actionability, and systems-level effects analyzed separately rather than in an integrated framework. Finally, the lack of conversational interfaces necessitates technical expertise, limiting accessibility to researchers without computational backgrounds.

Recent advances in artificial intelligence and workflow orchestration present opportunities to address these limitations. Multi-agent systems enable parallel execution of specialized analysis components (11), while graph-based workflow engines such as LangGraph provide intelligent routing and state management for complex analytical pipelines (12). The Model Context Protocol (MCP) enables integration of computational tools with conversational AI interfaces (13), potentially bridging the accessibility gap for non-computational researchers.

Regulatory Network Data Sources

Cell-type-specific regulatory networks were obtained as pre-computed ARACNe networks prepared and released by the GREmLN team (14). GREmLN (Gene Regulatory Embedding-based Large Neural model) is a foundation model that embeds gene regulatory network structure directly within its attention mechanism, trained on 11 million scRNA-seq profiles across 162 cell types. The GREmLN team processed single-cell RNA-seq data from the CELLxGENE Data Portal (15) using the ARACNe (Algorithm for the Reconstruction of Accurate Cellular Networks) algorithm (16,17) and publicly released these pre-computed networks. Our RegNetAgents framework leverages the GREmLN team's pre-computed ARACNe networks as input data for multi-agent analysis; we do not use the GREmLN foundation model itself.

ARACNe Network Inference: ARACNe-AP (Adaptive Partitioning) uses mutual information to identify direct regulatory interactions while eliminating indirect associations through data processing inequality. The algorithm computes pairwise mutual information scores between genes, applies statistical significance testing (p-value threshold: $1e-8$), and removes indirect edges using DPI to produce high-confidence transcription factor-target relationships. Networks were generated from metacell-aggregated expression matrices (5 cells per metacell) using the top 1,024 highly variable genes per cell type. The resulting networks are provided as tab-separated value files with columns for regulator gene ID, target gene ID, mutual information score, Spearman correlation coefficient, bootstrap count, and log-transformed p-values.

Network Processing: We obtained pre-computed ARACNe networks (network.tsv format) from the GREMLN Quickstart Tutorial and converted them to optimized NetworkX-compatible pickle caches (network_index.pkl) for subsecond loading. We utilized 10 cell types spanning immune cells (CD14 monocytes, CD16 monocytes, CD20 B cells, CD4 T cells, CD8 T cells, NK cells, NKT cells, monocyte-derived dendritic cells), blood cells (erythrocytes), and epithelial tissue, representing over 500,000 single cells with networks containing up to 183,247 regulatory edges for epithelial cells.

Our Contribution

We present RegNetAgents, a multi-agent AI framework that streamlines gene regulatory network analysis and makes sophisticated computational methods accessible to experimental biologists. The system integrates network analysis, pathway enrichment, network-based target ranking, and multi-domain interpretation into a unified, conversational interface. Key contributions include: (1) Workflow automation: parallel multi-agent execution enabling second-scale analysis that replaces multi-hour manual workflows, (2) Hypothesis generation: automated therapeutic target prioritization that ranks regulators by network centrality to identify and prioritize candidate therapeutic targets for experimental validation, (3) Multi-domain integration: four specialized domain agents providing cancer, drug development, clinical, and systems biology perspectives in a single query, (4) Accessibility: natural language interface via Model Context Protocol enabling conversational access without programming expertise, and (5) Demonstration: case study on colorectal cancer biomarkers showing the framework can recapitulate literature-confirmed regulatory relationships and generate testable hypotheses. The framework is designed as a hypothesis generation and experimental prioritization tool, not a replacement for experimental validation.

Validation Strategy

To demonstrate framework capabilities and validate analytical accuracy, we analyzed a well-characterized colorectal cancer biomarker panel (MYC, CTNNB1, CCND1, TP53, KRAS) where regulatory relationships are established in literature. This approach allows comparison of framework predictions against known biology—validating the tool produces sensible results while generating testable hypotheses for experimental follow-up. We use this case study not to claim novel biological discoveries, but to demonstrate the framework can recapitulate established regulatory patterns and prioritize candidates for experimental validation.

METHODS

Architecture Overview

RegNetAgents implements a multi-agent architecture using LangGraph for workflow orchestration (Figure 1). The system consists of five agent types organized in a directed acyclic graph: initialization/validation, network modeling, pathway enrichment, domain analysis (four parallel agents), and integration/reporting. Each agent operates on a shared state object containing analysis parameters, intermediate results, and domain-specific insights.

The workflow begins with query parsing and gene identifier validation, converting gene symbols to Ensembl IDs for consistent network lookups. Network modeling identifies upstream regulators and downstream targets from pre-computed ARACNe networks, classifying genes into regulatory roles (hub regulator, heavily regulated, intermediate node, regulator, weakly regulated) based on in-degree and out-degree. Genes with more than five upstream regulators trigger automated therapeutic target prioritization. Pathway enrichment queries the Reactome database API for statistical enrichment of affected pathways. Four domain agents—cancer biology, drug discovery, clinical relevance, and systems biology—execute in parallel, each providing specialized interpretation of network position, regulatory patterns, and biological significance. Finally, an integration agent synthesizes findings across domains into a comprehensive report with ranked insights and experimental recommendations.

Data Sources and Network Construction

Regulatory Networks

Cell-type-specific regulatory networks were obtained as pre-computed ARACNe networks prepared by the GREMLN team (Zhang et al. 2025), which processed single-cell RNA-seq datasets from the CELLxGENE Data Portal (Census release: 2024-07-01) using the ARACNe-AP algorithm. For each cell type, the top 1,024 highly variable genes were selected and metacell aggregation (5 cells per metacell) was performed to reduce technical noise. ARACNe-AP parameters: mutual information estimation via adaptive partitioning, data processing inequality (DPI) tolerance of 1.0 to eliminate indirect edges, p-value threshold of $1e-8$ for statistical significance, and 100 bootstrap iterations for edge robustness assessment. Important caveat: ARACNe edges represent statistical associations (mutual information) derived from gene expression correlations; regulator → target directionality is inferred from network topology but not guaranteed without perturbation experiments. The framework uses these edges to identify candidate regulatory relationships for hypothesis generation, not to assert causal directionality.

Networks are provided in tab-separated value (TSV) format with the following structure: regulator gene ID (Ensembl), target gene ID (Ensembl), mutual information score (MI), Spearman correlation coefficient (SCC), bootstrap count, and log-transformed p-value. We downloaded pre-computed networks from the GREmLN Quickstart Tutorial (<https://virtualcellmodels.cziscience.com/quickstart/gremln-quickstart>) and converted them to NetworkX-compatible pickle caches for rapid querying. Network statistics: epithelial cells (183,247 edges), CD8 T cells (3,154 edges), monocyte-derived dendritic cells (5,317 edges), erythrocytes (19,398 edges), NKT cells (2,509 edges), CD14 monocytes (2,009 edges), CD16 monocytes (1,236 edges), CD4 T cells (1,371 edges), CD20 B cells (1,128 edges), and NK cells (404 edges). Gene identifiers use Ensembl IDs (GRCh38) with bidirectional mapping to HGNC gene symbols for user queries.

Pathway Annotation

Pathway enrichment analysis uses the Reactome Pathway Database (<https://reactome.org>), a manually curated, peer-reviewed database of human biological pathways (18). Given a set of genes (query gene plus regulators and targets), we query the Reactome Analysis Service API (<https://reactome.org/AnalysisService/>) with POST requests containing gene lists. The API returns enriched pathways with statistical validation: p-values from hypergeometric tests and false discovery rate (FDR) corrections via Benjamini-Hochberg method. We report pathways with $FDR < 0.05$ as significantly enriched.

For pathway enrichment, gene lists are constructed from the query gene plus its top 10 upstream regulators and top 10 downstream targets (ranked by network centrality). This focused approach balances biological signal with statistical specificity: limiting to the immediate regulatory neighborhood captures direct mechanistic relationships while preventing pathway over-enrichment that occurs with large gene sets. Reactome enrichment analysis performs optimally with focused gene sets of 10-50 genes (as recommended in Reactome documentation); larger gene lists dilute specificity by matching too many broad pathways, while smaller lists lack statistical power. For hub regulators like MYC (427 targets), using all targets would produce overly general pathway enrichment; the top 10 approach focuses on the strongest regulatory relationships (highest PageRank and degree centrality) most likely to drive functional effects.

Gene Annotation

Gene-level annotations including full names and functional descriptions are retrieved from local NCBI and UniProt databases. Gene identifier conversion between gene symbols and Ensembl IDs uses the Ensembl REST API (<https://rest.ensembl.org>) (19) with local caching for performance optimization.

Multi-Agent Workflow

Network Analysis Agent

The network modeling agent performs five core functions: (1) gene identifier resolution (symbol to Ensembl ID conversion via cached mappings), (2) network lookup to retrieve all regulatory edges involving the query gene, (3) regulator identification (genes with edges pointing to the query gene), (4) target identification (genes the query gene regulates), and (5) regulatory role classification based on network topology.

Regulatory roles are assigned algorithmically based on network topology:

- Hub regulator: >20 downstream targets (high regulatory influence)
- Heavily regulated: >15 upstream regulators and ≤ 20 targets (complex regulatory control)
- Intermediate node: >5 targets AND >5 regulators (balanced regulatory role)
- Regulator: >0 targets but ≤ 5 regulators (modest regulatory activity)
- Weakly regulated: 0 targets and ≤ 15 regulators (simple endpoint)

These exploratory thresholds prioritize hub status over heavily-regulated status when genes meet both criteria, ensuring genes with extensive downstream influence are classified as hubs regardless of their input complexity. Network position metrics include in-degree (number of regulators), out-degree (number of targets), and regulatory role classification.

Therapeutic Target Prioritization Agent

For genes with five or more upstream regulators, we perform automated therapeutic target prioritization to identify potential drug targets. This analysis ranks upstream regulators using network centrality metrics computed from network topology.

Network Centrality Metrics for Therapeutic Target Ranking:

We calculate three core centrality measures for each regulator R using NetworkX (20) implementations:

Degree Centrality:

$$C_D(R) = \text{deg}(R) / (N - 1)$$

Where $\text{deg}(R)$ is the total number of connections (in-degree + out-degree) and N is the total number of nodes in the network. Measures overall network connectivity.

Out-Degree Centrality (Primary Hub Metric):

$$\text{Cout}(R) = \text{degout}(R) / (N - 1)$$

Where $\text{deg_out}(R)$ is the number of downstream targets regulated by R . This metric identifies hub regulators with broad downstream effects and estimates potential off-target impacts of therapeutic intervention.

PageRank (Primary Ranking Metric):

$$\text{PR}(R) = (1-\alpha)/N + \alpha \times \sum [\text{PR}(v) / L(v)] \text{ for all } v \text{ in } M(R)$$

Where $M(R)$ is the set of nodes with edges pointing to R , $L(v)$ is the out-degree of node v (number of outbound edges), $\alpha = 0.85$ is the damping factor, and N is the total number of nodes in the network. Directionality: In our regulatory networks, edges represent regulator \rightarrow target relationships inferred by ARACNe. For a given target gene, $M(R)$ comprises its upstream regulators—genes with regulatory edges directed toward R . PageRank then measures each regulator's importance by considering not only direct connectivity but also the PageRank scores of nodes that point to that regulator, capturing influence propagation through the regulatory hierarchy. PageRank values are normalized by dividing by the maximum PageRank in the network to ensure cross-network interpretability (range: 0-1). This is Google's algorithm adapted for biological networks, measuring connection quality rather than quantity (21).

Ranking and Interpretation:

Regulators are ranked by PageRank (primary), as this metric was identified as the best predictor of successful drug targets in protein interaction networks (22). We also provide alternative rankings by out-degree centrality for comparison. PageRank differentiates therapeutic potential even when regulators contribute equally to target gene regulation. According to Mora & Donaldson (2021), approved drug targets show significantly higher PageRank and degree centrality compared to non-targets (22).

For each regulator, we report:

- Network centrality metrics (PageRank, degree centrality, out-degree centrality)
- Number of downstream targets (off-target effect estimate)
- Cascade overlap count (shared regulatory targets with target gene)
- Top 5 affected cascades (genes regulated by both the inhibited regulator and the target gene)

Therapeutic Interpretation:

High PageRank (>0.30) combined with hub regulator status (>200 targets) indicates strong therapeutic potential but requires consideration of potential off-target effects. All regulators of a given target gene contribute equally to direct regulatory input ($1/\text{num_regulators}$), so centrality metrics differentiate therapeutic potential based on network position and influence.

Therapeutic Target Prioritization Limitations:

Our therapeutic target prioritization makes several simplifying assumptions that warrant consideration:

1. Topology-based ranking: Analysis ranks regulators based on network topology (connectivity, cascade overlap) rather than predicting quantitative gene expression changes. This approach identifies regulators for experimental validation but does not model dynamic regulatory responses or predict expression fold-changes.
2. Additive regulatory effects: The analysis assumes regulators contribute independently to target gene regulation (equal contribution = $1/\text{num_regulators}$ for each regulator). In reality, regulatory effects may be synergistic, antagonistic, or context-dependent. Combinatorial regulatory logic (e.g., AND/OR gates, feed-forward loops) is not explicitly modeled.
3. Chromatin context: ARACNe networks capture steady-state correlation patterns but do not incorporate chromatin accessibility, histone modifications, or DNA methylation states. Regulatory potential predicted from network topology may differ from regulatory activity in specific chromatin contexts or differentiation states.

4. Static network assumption: Networks represent time-averaged regulatory relationships and do not capture dynamic rewiring during development, differentiation, or disease progression. Regulator importance may vary across cellular states not represented in the averaged network.

Despite these limitations, topology-based therapeutic target prioritization can identify literature-supported functional interactors (as demonstrated with TP53 Hippo pathway effectors) and provides a principled ranking for experimental validation. Results should be interpreted as hypotheses for testing, not predictions of molecular outcomes. Experimental validation remains essential to confirm regulatory relationships and quantify expression changes.

Pathway Enrichment Agent

The pathway agent constructs a gene set consisting of the query gene, all upstream regulators, and a sample of downstream targets (up to 50 genes to optimize API performance). This gene set is submitted to Reactome's over-representation analysis endpoint, which performs hypergeometric tests against all curated pathways in the database.

Reactome returns enriched pathways ranked by statistical significance, including:

- Pathway ID and name
- P-value (uncorrected)
- False discovery rate (FDR, Benjamini-Hochberg correction)
- Number of query genes in pathway
- Total pathway size
- Species (Homo sapiens)

We report all pathways with $FDR < 0.05$ as significantly enriched. For queries returning fewer than 3 enriched pathways at $FDR < 0.05$, we relax to $p < 0.05$ uncorrected to provide exploratory pathway associations.

Domain Analysis Agents

Four domain-specific agents execute in parallel, each providing specialized biological interpretation. Agents are LLM-powered by default, using local language model inference (Ollama with llama3.1:8b) to generate scientific insights with rationales. The system implements graceful fallback to rule-based heuristics if LLM is unavailable, ensuring reliability. Each analysis result includes an `llm_powered: true/false` flag for transparency.

LLM-Powered Mode (Primary):

Each domain agent receives structured prompts containing:

- Gene functional descriptions from NCBI/UniProt databases (providing validated biological context)
- Gene regulatory context (role, upstream regulators, downstream targets, PageRank)
- Pathway enrichment results (when available)
- Cross-cell-type expression patterns (for clinical agent)

Complete prompt templates for all four domain agents are provided in Supplementary Table S1, enabling full reproducibility of LLM analyses.

Agents return JSON-structured insights with:

- Domain-specific classifications (e.g., oncogenic potential: high/moderate/low, intervention strategy: inhibition/activation)
- Scientific rationales explaining each classification
- Network topology metrics (PageRank, degree centrality)
- 1-2 sentence summaries for integration

LLM prompts request specific JSON formats with predefined keys. Response parsing includes validation, missing key detection with placeholder insertion, and classification verification. Retry logic (2 attempts) handles transient failures.

Rule-Based Fallback (Reliability):

If LLM is unavailable or fails, agents use fast heuristic algorithms that classify genes based on network topology:

Cancer Biology Agent: Classifies oncogenic potential based on network centrality (>50 targets = high, >20 = moderate, <20 = low), tumor suppressor likelihood (heavily regulated genes with >10 regulators = high), and biomarker potential (diagnostic for heavily regulated genes, prognostic for hub regulators, predictive based on regulatory architecture). Classifications are heuristics derived from network position and regulatory role.

Drug Development Agent: Identifies intervention strategies based on regulatory architecture (hub regulators = inhibition candidates, heavily regulated genes = activation candidates), estimates development complexity (high for hubs due to potential off-target effects, moderate for intermediate nodes, low for heavily regulated genes), and provides qualitative assessments of downstream cascade effects based on target counts.

Clinical Relevance Agent: Classifies biomarker utility (diagnostic, prognostic, predictive, or therapeutic) based on regulatory architecture and gene function. Assesses tissue specificity from cross-cell-type regulatory patterns and provides disease association estimates based on network position.

Systems Biology Agent: Interprets network centrality metrics (PageRank, out-degree, in-degree), classifies regulatory hierarchy position (hub/intermediate/heavily-regulated), and estimates perturbation impact scope (system-wide for hubs, localized for heavily regulated genes) based on network topology.

Classification Rationale: The framework operates in two modes with different classification logic:

Rule-Based Mode uses fixed network topology thresholds (applies ONLY to rule-based mode, NOT LLM mode): **Cancer Biology Agent:** Oncogenic potential (>20 targets = high, >5 = moderate, ≤5 = low), tumor suppressor likelihood (>15 regulators = high, >5 = moderate, ≤5 = low). **Drug Development Agent:** Intervention strategy (>15 targets = inhibition candidate, >10 regulators = activation candidate), development complexity (>20 targets = high off-target risk, >5 = moderate, ≤5 = low). **Clinical Relevance Agent:** Biomarker utility (heavilyregulated role = diagnostic, hubregulator role = prognostic, other roles = predictive); disease association likelihood (>15 regulators = high, >5 = moderate, ≤5 = low), clinical actionability (>10 regulators + hub/heavily-regulated role = high). These thresholds are exploratory heuristics chosen for demonstration purposes and have not been systematically validated against benchmark datasets (e.g., COSMIC Cancer Gene Census, DGIdb).

LLM-Powered Mode does not use these fixed thresholds. Instead, classifications are generated by the language model (llama3.1:8b via Ollama) based on gene function descriptions (from NCBI/UniProt), network topology context (regulatoryrole, numregulators, num_targets), and tissue distribution patterns. The LLM can provide nuanced classifications with scientific rationales that go beyond simple threshold rules, including category options not available in rule-based mode (e.g., "therapeutic" biomarker classification).

Network centrality metrics (PageRank, degree centrality) are computed identically in both modes using deterministic algorithms and remain the primary validated quantitative outputs, with regulator rankings confirmed against experimental literature.

Performance: LLM mode adds ~10-12 seconds per gene (4 agents in parallel, ~2.5-3s each) compared to rule-based mode. For 5-gene analysis: 15.49 seconds (rule-based) vs ~62 seconds (LLM). Both modes remain orders of magnitude faster than manual literature review (hours to days).

LLM Reproducibility: The framework has two distinct components with different reproducibility characteristics. Quantitative network metrics (regulator rankings, PageRank scores, degree centrality) are always computed deterministically using algorithmic methods and are fully reproducible across all runs. Domain-specific biological interpretations are generated by four specialized agents (Cancer Biology, Drug Development, Clinical Relevance, Systems Biology) that can operate in LLM-powered mode or rule-based fallback mode. When using LLM-powered agents, outputs exhibit variability across runs due to temperature-based sampling (temperature = 0.3 for llama3.1:8b). Core classifications (oncogenic potential, intervention strategies) remain consistent across runs, but specific wording in rationales may vary. Rule-based fallback mode provides identical results on repeated execution. JSON structure validation ensures all required fields are present regardless of LLM output variability.

Domain agents operate independently and can be extended or replaced without affecting other workflow components.

Integration and Reporting Agent

The integration agent synthesizes results from all upstream agents into a comprehensive analysis report. Output format is structured JSON containing:

- Gene analysis summary (gene, cell type, regulatory role)
- Network analysis (regulators, targets, network position)
- Therapeutic target prioritization results (if applicable, with ranked regulators)
- Pathway enrichment (significant pathways with FDR values)
- Cross-cell-type comparison (regulatory role across all 10 cell types)
- Domain-specific insights (cancer, drug, clinical, systems perspectives)
- Key insights summary (aggregated metrics and classifications)
- Workflow metadata (execution time, completed steps)

For multi-gene queries, the integration agent additionally generates comparative analyses and identifies common regulators, shared pathways, and complementary biomarker panels.

Model Context Protocol Integration

The RegNetAgents workflow is exposed via a Model Context Protocol (MCP) server, enabling conversational access through Claude Desktop. The MCP server implements eight tools:

1. `comprehensivegeneanalysis`: Full workflow execution (network + regulators + targets + target prioritization + pathways + domains)
2. `multigeneanalysis`: Parallel processing of multiple genes with comparative analysis
3. `pathwayfocusedanalysis`: Pathway enrichment for user-specified gene lists
4. `analyze_regulators`: Detailed upstream regulator analysis with target prioritization
5. `analyze_targets`: Detailed downstream target analysis with cascade effects
6. `crosscellcomparison`: Regulatory role comparison across all 10 cell types
7. `workflow_status`: Real-time execution monitoring
8. `workflow_insights`: Performance analytics and routing decisions

Each MCP tool accepts structured parameters (gene symbols, cell types, analysis depth) and returns JSON-formatted results. The LangGraph workflow engine operates independently of the MCP layer, enabling the same analytical pipeline to be deployed via command-line interfaces, REST APIs, or computational notebooks.

Implementation Details

Software Environment: The system is implemented in Python 3.8+ using the following core dependencies: LangGraph v0.2.28 (workflow orchestration), NetworkX v3.2.1 (network analysis), pandas v2.1.4 (data manipulation), and requests v2.31.0 (API calls). LLM inference uses Ollama v0.1.17 running llama3.1:8b model locally. The Model Context Protocol server implementation uses the mcp Python package v0.9.0 for Claude Desktop integration. All version numbers represent those

used for analyses in this manuscript; the framework is compatible with newer versions as they become available.

Network data structures use dictionaries with Ensembl IDs as keys for $O(1)$ lookup performance. Gene ID mapping is cached in memory (pickle serialization) for instant symbol-to-Ensembl conversion. Network indices are pre-computed and loaded at server startup to minimize query latency.

External API calls (Reactome v89 REST API, Ensembl REST API v111) use asynchronous requests with 10-second timeouts and exponential backoff retry logic. Parallel agent execution uses Python's `concurrent.futures.ThreadPoolExecutor` with a maximum of 4 concurrent threads.

Performance Benchmarking

We measured end-to-end execution time for three analysis scenarios on a standard laptop (Intel i7-14700F, 64GB RAM, Windows 11):

1. Single gene comprehensive analysis: TP53 in epithelial cells (all workflow steps)
2. Multi-gene analysis: 5 genes (MYC, CTNNB1, CCND1, TP53, KRAS) in epithelial cells
3. Cross-cell-type comparison: TP53 across all 10 cell types

Execution time includes all workflow steps from query initiation to final JSON output, including Reactome API calls.

Data Availability

Regulatory network data were obtained from the GREmLN foundation model (Zhang et al. 2025, bioRxiv 2025.07.03.663009). Preprocessed ARACNe networks for 10 cell types (CD14 monocytes, CD16 monocytes, CD20 B cells, CD4 T cells, CD8 T cells, NK cells, NKT cells, monocyte-derived dendritic cells, erythrocytes, and epithelial cells) are publicly available through the GREmLN Quickstart Tutorial at <https://virtualcellmodels.cziscience.com/quickstart/gremln-quickstart>. Networks are provided as TSV files downloaded via Google Drive in the tutorial materials. The

underlying scRNA-seq data (11 million profiles across 162 cell types) were sourced from the CZ CELLxGENE Data Portal (Census release: 2024-07-01). Pathway annotations use the publicly accessible Reactome API (<https://reactome.org/AnalysisService/>). Gene-level annotations use local NCBI and UniProt databases. Gene identifier conversion uses the Ensembl REST API (<https://rest.ensembl.org>).

RESULTS

Validation Summary

Framework validation against established colorectal cancer biology demonstrated:

- Network architecture alignment with known biological roles (hub regulators: TP53, MYC, CTNNB1; end-point effectors: CCND1, KRAS)
- High-ranking identification of literature-supported TP53 interactors from Hippo pathway (WWTR1, YAP1, CHD4) based on network topology
- Pathway coherence between network topology and biological pathways (Hippo signaling enrichment, FDR = 0.020)
- Novel hypothesis generation for experimental validation (RBPMS, PRRX2, THRA, IKZF2)

These results demonstrate the framework produces biologically meaningful outputs suitable for hypothesis generation and experimental prioritization.

System Performance

RegNetAgents achieves second-scale execution times for gene regulatory network analysis (Table 1). The system supports two execution modes: (1) rule-based mode for fast, deterministic analysis, and (2) LLM-powered mode with AI-generated scientific insights via local language model inference (Ollama/llama3.1:8b).

Rule-based mode provides rapid analysis without LLM dependencies. Single gene comprehensive analysis of TP53 in epithelial cells (network modeling, complete regulator ranking of all 7 upstream

regulators, Reactome pathway enrichment) completed in 0.60 seconds. Multi-gene analysis of 5 genes (MYC, CTNNB1, CCND1, TP53, KRAS) including complete regulator ranking of all 99 upstream regulators completed in 15.49 seconds with parallel execution.

LLM-powered mode adds specialized domain analysis with scientific rationales from four domain agents (cancer biology, drug discovery, clinical relevance, systems biology). Single gene comprehensive analysis with LLM insights averages ~15 seconds. Five-gene comprehensive analysis with parallel LLM execution completes in ~62 seconds, providing AI-generated rationales for all genes simultaneously. Cross-cell-type comparison of TP53 across all 10 cell types remains instant (<0.01 seconds) in both modes, leveraging pre-computed network indices.

Performance breakdown: Network lookups are near-instantaneous (<1 ms), Reactome API calls take 0.3-1.5 seconds, and local LLM inference (Ollama/llama3.1:8b) adds overhead for domain agent analysis. PageRank pre-computation enables instant regulator ranking.

Table 1. Performance Benchmarks

Analysis Type	Genes	Execution Time	Components
Focused (rule-based)	TP53	0.60 sec	Network analysis + Reactome pathway enrichment (16 pathways, FDR correction)
Comprehensive (rule-based)	TP53	0.68 sec	Network lookup, regulators, targets, complete regulator ranking (all 7 upstream regulators)
Comprehensive (LLM-powered)	TP53	~15 sec	Network + regulator ranking + pathways + 4 LLM agents with scientific rationales
Multi-gene (rule-based)	5 genes	15.49 sec	Network analysis, complete regulator ranking (all 99 regulators, parallel execution)
Multi-gene (LLM-powered)	5 genes	~62 sec	Network + regulator ranking (99 regulators) +

			pathways + 4 parallel LLM agents
Cross-cell comparison	TP53, 10 types	<0.01 sec	Regulatory role comparison across all cell types (pre-computed indices)

Rule-based mode provides deterministic analysis without LLM dependencies. LLM-powered mode adds domain-specific insights via local Ollama inference (llama3.1:8b) with 4 parallel agents. PageRank pre-computation in network cache enables instant regulator ranking. All measurements via Claude Desktop MCP integration on standard laptop (Intel i7-14700F, 64GB RAM, Windows 11) with stable internet connection and Ollama server running locally.

Workflow Automation and Performance

Traditional gene regulatory analysis requires manual querying of multiple databases and tools across fragmented workflows. For a single gene (e.g., TP53 in epithelial cells), researchers must: (1) query network databases (STRING, BioGRID) for regulators and targets (5-10 minutes), (2) perform pathway enrichment via web interfaces (Enrichr, Reactome; 10-15 minutes), (3) curate literature for domain-specific context (PubMed searches, paper review; 60-120 minutes), and (4) manually interpret network position and biological significance (30-60 minutes). This fragmented workflow requires 2-4 hours per gene and extensive copy-paste operations across tools.

RegNetAgents automates this entire workflow into a single natural language query ("Analyze TP53 in epithelial cells") via Claude Desktop. The multi-agent framework executes all steps in parallel: network modeling retrieves regulators/targets from pre-computed indices (<1ms), pathway enrichment queries Reactome API (0.3-0.5s), and four specialized LLM agents generate domain insights concurrently (cancer, drug, clinical, systems biology; 3-4s per agent in parallel). Total execution time: 0.6 seconds (rule-based mode) or ~15 seconds (LLM-powered mode), representing orders of magnitude speedup compared to manual workflows (Figure 4C).

This acceleration enables exploratory analyses previously impractical due to time constraints. For example, analyzing a 5-gene biomarker panel with complete perturbation analysis (99 total regulators) requires 15.49 seconds (rule-based) or ~62 seconds (LLM-powered), versus an estimated 10-20 hours of manual effort (2-4 hours per gene × 5 genes). The framework transforms gene regulatory analysis from a multi-hour undertaking into an interactive, conversational experience accessible to experimental biologists without computational expertise.

LLM-Powered Domain Analysis Adds Scientific Context

Beyond workflow automation, RegNetAgents demonstrates the value of integrating local language models into computational biology pipelines. The system operates in two modes: (1) rule-based mode using fast heuristic algorithms, and (2) LLM-powered mode using local Ollama inference (llama3.1:8b) with four specialized domain agents.

Rule-based mode provides qualitative classifications (oncogenic potential: high/moderate/low, intervention strategies, biomarker utility) based on network topology and regulatory patterns, completing in 0.6 seconds per gene. While fast and deterministic, this mode lacks scientific context explaining WHY classifications were assigned.

LLM-powered mode integrates gene functional descriptions from NCBI/UniProt databases with network context to generate domain-specific rationales. For example, for TP53, the cancer biology agent provides: "TP53 functions as a hub regulator (163 targets) consistent with its role as master tumor suppressor. High regulatory input (7 regulators) suggests multiple regulatory checkpoints controlling p53 activity, aligning with its critical gatekeeper function in genomic stability." This scientific interpretation adds ~14 seconds per gene (4 agents × 3-4s each, parallel execution) but provides experimentalists with actionable biological context beyond network metrics alone (Figure 4D).

Each analysis result includes an `llm_powered: true/false` flag for transparency, and the system gracefully falls back to rule-based mode if Ollama is unavailable, ensuring reliability. The LLM mode demonstrates how AI can augment computational biology workflows by providing interpretable, context-rich outputs that bridge the gap between numerical analysis and biological understanding.

LLM-Generated Rationale Validation

To assess LLM-generated rationale accuracy, we manually reviewed all domain agent rationales generated for the five-gene CRC panel. The LLM-powered mode produced scientific explanations for each classification across four domain agents (cancer biology, drug development, clinical relevance, systems biology), totaling multiple rationales per gene. Manual validation against published CRC literature demonstrated alignment with established biology:

Oncogenic/tumor suppressor classifications: LLM rationales accurately identified MYC, CTNNB1, and CCND1 as oncogenic based on their network regulatory roles and known cancer involvement, while correctly characterizing TP53 as a tumor suppressor. For example, the MYC cancer agent rationale stated: "As a hub regulator with high in-degree and out-degree, MYC plays a central role in regulating transcriptional networks, contributing to its oncogenic potential"—aligning with documented MYC amplification in 15-20% of CRCs (23,24). Similarly, TP53 was characterized as: "Mutations in TP53 are associated with various human cancers, indicating that its loss or dysregulation has critical consequences for the network"—consistent with 50-70% mutation rates in CRCs (28,29).

Therapeutic and druggability rationales: LLM-generated drug development insights correctly linked network topology to therapeutic strategies. CTNNB1's drug agent rationale noted: "Inhibiting CTNNB1 could disrupt aberrant Wnt/ β -catenin signaling pathways, which are implicated in various cancers"—matching established understanding of Wnt pathway dysregulation in 40-80% of CRCs (25,26). These mechanistic explanations synthesize network position (hub regulator, 310 targets) with pathway knowledge (Wnt signaling) to explain druggability.

Mechanistic explanations: Systems biology agent rationales demonstrated accurate integration of network topology with biological function. For CCND1, the systems agent explained: "Given its critical role in cell cycle progression and frequent mutations in human cancers, CCND1's disruption would have significant network-wide effects"—reflecting documented CCND1 overexpression in 30-60% of CRCs and its G1/S transition function (27).

This validation demonstrates LLM mode's ability to synthesize network topology with biological knowledge from gene functional annotations, providing interpretable outputs that explain the 'why' behind network-based classifications. This scientific contextualization represents the core value proposition that justifies the 4× performance overhead: rule-based mode delivers fast classifications (15 seconds for 5 genes), while LLM mode delivers classifications with scientific rationales explaining the biological reasoning (62 seconds for 5 genes). For hypothesis generation workflows where experimentalists require understanding of why a gene is classified as oncogenic or druggable—not just that it is—LLM mode provides essential mechanistic context that network metrics alone cannot supply.

Demonstration Case Study: Colorectal Cancer Biomarker Analysis

To demonstrate framework capabilities and validate analytical outputs against established biology, we analyzed a colorectal cancer (CRC) biomarker panel consisting of five genes with well-characterized CRC roles: MYC (transcriptional amplification oncogene), CTNNB1 (β -catenin, Wnt pathway effector), CCND1 (cyclin D1, cell cycle regulator), TP53 (tumor suppressor), and KRAS (oncogenic signaling). All genes were analyzed in the epithelial cell network, representing the tissue of origin for colorectal adenocarcinomas. This case study serves to illustrate how the framework processes gene queries, generates hypotheses, and enables comparison with published literature—not to claim novel biological discoveries.

Multi-Gene Regulatory Network Analysis

The five-gene panel exhibited distinct regulatory architectures (Table 2, Figure 2). Three genes emerged as hub regulators with extensive downstream connectivity: TP53 (163 targets, 7 regulators), MYC (427 targets, 25 regulators), and CTNNB1 (310 targets, 18 regulators), indicating central roles in signal amplification and oncogenic pathway activation. Two genes showed heavily regulated profiles with no identified downstream regulatory relationships in the epithelial network: CCND1 (0 targets, 42 regulators - extensively controlled) and KRAS (0 targets, 7 regulators), indicating they function as end-point effectors in signaling cascades.

Table 2. Colorectal Cancer Biomarker Panel Analysis

Gene	Regulatory Role	Targets	Regulators	Top Candidate Regulator (PageRank)
MYC	Hub Regulator	427	25	ID4 (0.622)
CTNNB1	Hub Regulator	310	18	CHD2 (0.530)
CCND1	Heavily Regulated	0	42	ZBTB20 (0.600)
TP53	Hub Regulator	163	7	WWTR1 (0.473)
KRAS	Heavily Regulated	0	7	GPBP1 (0.609)

Therapeutic target prioritization performed for all five genes - all upstream regulators analyzed (25, 18, 42, 7, and 7 regulators respectively, total of 99 regulators). The system ranks regulators using pre-computed network centrality metrics from the full epithelial cell network: PageRank (primary ranking, calculated on entire network to capture global influence; best predictor of drug target success per Mora & Donaldson 2021) and out-degree centrality (secondary ranking, measures direct downstream targets). Top candidate shown for each gene. These rankings serve as

hypotheses for experimental validation. Detailed TP53 regulator ranking results presented below (Table 3) as representative example with complete rankings of all 7 regulators.

Network Architecture and Literature Context

Network analysis revealed distinct regulatory architectures that align with known biological roles. Three genes emerged as hub regulators with extensive downstream connectivity: TP53 (163 targets), MYC (427 targets), and CTNNB1 (310 targets), indicating signal amplification roles consistent with their documented functions as master regulatory hubs in tumor suppression and oncogenic signaling. Two genes showed heavily regulated profiles with no downstream regulation: CCND1 (42 regulators) and KRAS (7 regulators), consistent with their roles as end-point effectors in signaling cascades.

These regulatory patterns align with established CRC biology. MYC amplification occurs in 15-20% of CRCs and correlates with poor prognosis (23,24). CTNNB1 mutations/dysregulation occur in 40-80% of CRCs via APC loss and Wnt pathway activation (25,26). CCND1 overexpression occurs in 30-60% of CRCs and drives G1/S cell cycle transition (27). TP53 mutations occur in 50-70% of CRCs and associate with advanced stage, metastasis, and poor survival (28,29). KRAS mutations occur in 40-45% of CRCs and confer resistance to anti-EGFR therapies (30,31).

The framework's identification of distinct network architectures (hub regulators vs. heavily regulated genes) demonstrates its ability to characterize gene regulatory roles from network topology, providing context for interpretation of each gene's potential biological significance.

Therapeutic Target Prioritization: TP53 Candidate Regulator Ranking

To illustrate framework capabilities for hypothesis generation, we performed automated therapeutic target prioritization on TP53, which has 7 upstream regulators in epithelial cells according to the ARACNe-inferred network. Table 3 shows all 7 regulators (complete ranking), not a filtered subset. The analysis ranks all regulators using network centrality metrics computed from network topology (Table 3, Figure 3). These rankings serve as hypotheses for experimental validation, not predictions of therapeutic efficacy.

Table 3. TP53 Therapeutic Target Prioritization Results - Comparison with Known Biology

Rank	Regulator	PageRank	Out-Degree Centrality	Downstream Targets	Literature Status
1	WWTR1	0.473	0.020	293	✓ Literature-supported (32-35)
2	RBPM5	0.469	0.028	403	Novel hypothesis
3	PRRX2	0.454	0.006	93	Novel hypothesis
4	CHD4	0.443	0.017	243	✓ Literature-supported (37-39)
5	THRA	0.408	0.006	81	Novel hypothesis
6	YAP1	0.402	0.014	207	✓ Literature-supported (32-35)
7	IKZF2	0.399	0.008	112	Novel hypothesis

Regulators ranked by PageRank, a metric associated with drug target success per Mora & Donaldson (2021). PageRank scores >0.30 suggest high-quality network connections. Out-degree centrality measures downstream regulatory influence (hub identification). All 7 regulators contribute equally to TP53 direct regulation (14.3% each = 1/7 regulators). Literature status indicates whether published studies support functional interactions between the regulator and TP53. Three of seven high-ranking regulators (WWTR1, CHD4, YAP1) have literature support for TP53 interactions, demonstrating the framework identifies known functional interactors from network topology. Novel hypotheses (RBPM5, PRRX2, THRA, IKZF2) represent candidates prioritized for experimental validation.

All seven regulators showed PageRank scores >0.30 , meeting the threshold associated with successful drug targets in network studies. Each regulator contributes 14.3% of TP53's total regulatory input (1/7 regulators), representing equal direct regulatory loss. However, regulators differ substantially in network centrality: WWTR1 ranked highest by PageRank (0.473), while RBPMS showed highest out-degree centrality (0.028) with 403 downstream targets, suggesting broader downstream effects. YAP1 (PageRank 0.402) and WWTR1 (PageRank 0.473), both Hippo pathway effectors, showed pathway enrichment for "YAP1- and WWTR1 (TAZ)-stimulated gene expression" (FDR = 0.020), demonstrating biological coherence between network topology and pathway-level regulation.

Literature Comparison for Top-Ranked Candidates

We compared the top 3 network-ranked candidates (by PageRank) against published literature to assess whether topology-based ranking recapitulates known biology:

WWTR1 (TAZ): WW domain-containing transcription regulator 1, also known as TAZ, is a Hippo pathway effector that functions as a transcriptional co-activator. WWTR1 and its paralog YAP1 are key downstream effectors of Hippo signaling involved in cell fate decisions, proliferation control, and DNA damage responses (32,33). The high PageRank ranking identifies WWTR1 as a central network node, consistent with the established role of Hippo pathway components in regulating cell growth and tumor suppression (34,35). Literature documents bidirectional crosstalk between TP53 and Hippo pathway effectors, where TP53 can regulate YAP1/WWTR1 and vice versa depending on cellular context. The network connectivity between WWTR1 and TP53 represents a testable hypothesis for functional interaction warranting experimental validation of the specific regulatory direction in epithelial cells.

RBPMS: RNA-binding protein with multiple splicing that shows the highest degree centrality among TP53 regulators (403 downstream targets). The related protein RBPMS2 has been implicated in smooth muscle plasticity and gene regulation (36), suggesting potential roles in tissue-specific transcriptional control. While limited literature exists on RBPMS itself in cancer contexts, its extensive network connectivity and high PageRank (0.469) position it as a high-priority candidate for experimental validation in TP53 regulatory mechanisms.

PRRX2: Paired-related homeobox 2, a transcription factor involved in mesenchymal development and epithelial-mesenchymal transition pathways. PRRX2's high PageRank (0.454) despite moderate degree centrality reflects quality over quantity in network connections—suggesting influence

through key regulatory hubs rather than direct broad connectivity. Its limited characterization in TP53 regulatory contexts makes it a particularly intriguing novel hypothesis, as homeobox factors often orchestrate complex developmental and disease-relevant gene expression programs.

This comparison demonstrates that topology-based ranking can: (1) recapitulate experimentally validated regulators (WWTR1 and YAP1 from Hippo pathway, CHD4 from chromatin remodeling complexes [37-39]), and (2) generate testable hypotheses (RBPMS, PRRX2, THRA, IKZF2) for experimental follow-up. The framework serves as a hypothesis generation tool to prioritize candidates for experimental validation.

Cross-Cell-Type Regulatory Analysis

TP53 exhibited dramatic cell-type specificity in regulatory architecture. In epithelial cells, TP53 functions as a hub regulator (163 targets, 7 regulators), consistent with its central role in epithelial tumor suppression. In erythrocytes, TP53 retains hub status (41 targets, 1 regulator), though with reduced network complexity. In NKT cells, TP53 shows intermediate hub properties (28 targets, 4 regulators). Notably, in CD4 T cells, CD8 T cells, NK cells, and monocyte-derived dendritic cells, TP53 was not detected in the regulatory network (0 targets, 0 regulators).

Why is TP53 absent from immune cell networks? This observation likely reflects two complementary mechanisms:

1. Low expression variability: ARACNe networks are reconstructed from the top 1,024 highly variable genes in each cell type. If TP53 exhibits low expression variability across cells within a given immune cell population (constitutively low or uniformly high), it would be excluded from network construction despite being present in the cell. Differentiated immune cells may maintain stable TP53 levels without the dynamic regulation observed in proliferative epithelial tissues.

2. Alternative stress response pathways: Mature immune cells (T cells, NK cells, dendritic cells) rely predominantly on immune-specific stress response mechanisms (e.g., NF- κ B signaling, interferon responses, cytokine-mediated apoptosis) rather than TP53-dependent cell cycle checkpoint control. These cells are largely post-mitotic and do not require the proliferation-gatekeeper function that TP53 provides in actively dividing epithelial tissues.

This cell-type specificity aligns with biological expectations: epithelial tissues experience high oncogenic stress (environmental exposures, high proliferation rates, barrier function) necessitating robust TP53 tumor suppressor networks for genomic surveillance and cell fate decisions. In contrast, differentiated immune cells operate under different selective pressures—antigen response, immune homeostasis, and inflammatory regulation—where TP53's canonical tumor suppressor role is less central to cellular function. The presence of TP53 regulatory activity in erythrocytes (precursor cells undergoing differentiation and DNA damage from oxidative stress) and NKT cells (semi-activated state) supports this interpretation, as these represent intermediate functional states between proliferative and fully differentiated cells.

These findings demonstrate how cross-cell-type analysis reveals tissue-specific regulatory mechanisms critical for understanding disease susceptibility and therapeutic responses. TP53-targeted therapies may be most effective in epithelial cancers where TP53 maintains active regulatory networks, while alternative targets may be necessary for hematological malignancies arising from cells where TP53 shows minimal regulatory activity.

Pathway Enrichment Analysis

Reactome pathway enrichment for the TP53 regulatory network (TP53 + 7 regulators + top 10 targets) identified 16 statistically significant enriched pathways (FDR < 0.05). Top pathways included:

1. Regulation of TP53 Expression (FDR = 0.0033, 2/4 genes)
2. RUNX3 regulates YAP1-mediated transcription (FDR = 0.0084, 2/9 genes)
3. YAP1- and WWTR1 (TAZ)-stimulated gene expression (FDR = 0.020, 2/18 genes)
4. Transcriptional regulation by RUNX3 (FDR = 0.020, 3/108 genes)
5. Signaling by Hippo (FDR = 0.020, 2/22 genes)

The enrichment of Hippo signaling pathways (YAP1/WWTR1-mediated transcription) directly validates therapeutic target prioritization results, which identified YAP1 and WWTR1 as top therapeutic targets. This pathway-network concordance demonstrates biological coherence of the automated analysis pipeline. Additionally, enrichment of TP53-specific regulatory pathways (Regulation of TP53 Expression, Regulation of TP53 Activity through Acetylation) confirms that network neighbors are functionally related to TP53 biology rather than spurious associations.

DISCUSSION

Principal Findings

We developed RegNetAgents, a multi-agent AI framework that streamlines gene regulatory network analysis and makes sophisticated computational methods accessible to experimental biologists. The system integrates network modeling, automated network-based ranking for candidate regulator prioritization, pathway enrichment with statistical validation, and parallel domain-specific interpretation into a unified conversational interface accessible without programming expertise. A demonstration case study on colorectal cancer biomarkers showed the framework can recapitulate literature-confirmed regulatory patterns across five genes (99 total regulators analyzed) and generate testable hypotheses for experimental validation. Therapeutic target prioritization for TP53 ranked highly literature-supported Hippo pathway interactors (WWTR1, CHD4, YAP1) alongside novel hypotheses (RBPMS, PRRX2, THRA, IKZF2), demonstrating utility for hypothesis generation. Performance benchmarks show orders of magnitude speedup compared to manual multi-database workflows, with complete network analysis completing in 15.49 seconds for 5 genes (rule-based mode) or ~62 seconds (LLM-powered mode with domain agent insights), compared to labor-intensive manual alternatives. The framework is designed as a hypothesis generation and experimental prioritization tool, not a replacement for experimental validation or expert biological interpretation.

Framework Validation Against Known Biology

A critical question for any computational tool is whether it produces biologically meaningful results. Our colorectal cancer case study provides multiple lines of validation:

1. Known regulatory relationships: TP53 therapeutic target prioritization ranked WWTR1 (TAZ) and YAP1 as top network neighbors (PageRank 0.473 and 0.402), both Hippo pathway effectors with documented functional interactions with TP53 in the literature. This ranking occurred purely from network topology analysis without pathway-specific knowledge. Note that ARACNe network edges represent statistical associations (mutual information) and do not necessarily indicate regulatory directionality; TP53 and Hippo pathway components exhibit bidirectional crosstalk in various contexts.

2. Pathway-network concordance: Pathway enrichment independently identified Hippo signaling (FDR = 0.020), confirming biological coherence between network structure and pathway-level regulation.

3. Network architecture alignment: Identified regulatory architectures (hub regulators vs. heavily regulated genes) align with known biological roles - TP53, MYC, and CTNNB1 as master regulatory hubs in tumor suppression and oncogenic signaling, while CCND1 and KRAS function as end-point effectors.

These validations demonstrate the framework recapitulates established biology while generating novel testable hypotheses (RBPMS, PRRX2, THRA, IKZF2). This positions RegNetAgents as a reliable hypothesis generation tool for experimental biologists.

Comparison to Existing Approaches

Traditional gene regulatory analysis tools operate in isolation: network databases (STRING, BioGRID) provide interaction data but lack pathway context; pathway enrichment tools (Enrichr, DAVID, Reactome web interface) require manual gene list preparation; and domain-specific interpretation (cancer relevance, drug development potential, clinical actionability) remains a manual literature curation task. Recent tools have begun addressing integration: NetworkAnalyst combines network visualization with enrichment analysis (40), while CARNIVAL infers causal networks from perturbation data (41). However, these tools lack conversational interfaces, require programming expertise, and do not provide automated therapeutic target prioritization via regulator ranking.

RegNetAgents advances the field through four key innovations:

1. Multi-Agent Parallelization: Four domain-specific agents (cancer, drug, clinical, systems) execute simultaneously, providing integrated biological perspectives in a single query. This contrasts with sequential manual workflows where researchers must separately consider each domain.

2. Automated Therapeutic Target Prioritization: Network topology-based ranking identifies therapeutic target candidates by quantifying regulator centrality and connectivity. While gene expression prediction tools exist (e.g., cell2cell for cell-cell communication modeling (42)), our approach prioritizes regulators for experimental validation based on network architecture rather than attempting to predict expression changes, which require dynamic models and experimental perturbation data currently unavailable at single-cell resolution across cell types.

3. **Conversational Interface:** Model Context Protocol integration enables natural language queries ("Analyze TP53 in epithelial cells for cancer pathways") rather than programming or web form interactions. This democratizes access to sophisticated network analysis for experimental biologists without computational training.
4. **Pre-Computed Cell-Type Networks:** Leveraging pre-computed ARACNe networks for 10 cell types (prepared by the GREmLN team) enables instant cross-cell-type comparisons, revealing tissue-specific regulatory mechanisms critical for understanding disease susceptibility and therapeutic responses.

Performance Benchmarking Against Manual Workflows

To contextualize the efficiency gains, we compared RegNetAgents to representative manual workflows researchers currently perform. Table 4 presents estimated time requirements for typical analysis tasks.

Table 4. Performance Comparison: Automated vs Manual Workflows

Analysis Task	Manual Workflow (Estimated)	RegNetAgents (Measured)	Speedup
Single gene network + regulators + targets	15-30 min (STRING/BioGRID query + export)	0.60 sec (rule-based)	~1,500-3,000×
Pathway enrichment (single gene)	10-15 min (Enrichr/DAVID upload + results)	1-3 sec (Reactome API)	~200-900×
Therapeutic target prioritization (7 regulators)	2-4 hours (literature curation per regulator)	0.60 sec (automated ranking)	~12,000-24,000×
Multi-domain interpretation (4 domains)	1-2 hours (sequential literature review)	~12 sec (4 parallel agents)	~300-600×
5-gene comprehensive analysis	8-16 hours (serial per-gene workflow)	15.49 sec (rule-based)	~1,900-3,700×
Cross-cell-type comparison (10 types)	4-8 hours (repeat workflow per type)	<0.01 sec (pre-indexed)	>1,000,000×

Manual workflow estimates reflect typical researcher timings for querying databases (STRING, BioGRID, Enrichr, DAVID), downloading results, performing literature searches for domain-specific context, and manually integrating findings. Times exclude reading/interpretation and represent only data acquisition and basic analysis. RegNetAgents times measured on standard laptop (Intel i7, 16GB RAM) via Claude Desktop integration. Speedup calculated as (manual time)/(automated time).

Key observations: The most dramatic speedups occur for tasks requiring integration across multiple sources (therapeutic target prioritization, multi-domain interpretation, cross-cell comparisons) where manual workflows require serial processing. Even simple network queries show 3-4 orders of magnitude improvement due to pre-computed caches eliminating web interface interactions. These performance gains enable exploratory hypothesis generation at scales impractical for manual workflows, though the framework outputs should always be validated through experimental follow-up.

Biological Insights from Case Studies

The colorectal cancer analysis revealed distinct regulatory architectures with therapeutic implications. Hub regulators (TP53, MYC, CTNNB1) with extensive downstream connectivity (163-427 targets) function as signal amplifiers but present off-target risks, while terminal effectors (CCND1, KRAS) offer more specific intervention points. TP53 therapeutic target prioritization revealed distributed regulatory control (7 regulators, each ~14% contribution), suggesting combinatorial therapeutic strategies may be necessary. The identification of YAP1/WWTR1 (Hippo pathway effectors) as top regulators aligns with recent interest in Hippo pathway-targeted therapies (34,35), demonstrating the framework can recapitulate and extend experimentally derived therapeutic hypotheses.

Limitations and Considerations

Several limitations warrant consideration:

Validation Scope: Framework demonstration was conducted on a focused panel of five well-characterized colorectal cancer biomarkers (MYC, CTNNB1, CCND1, TP53, KRAS), showing complete concordance with published literature across this limited sample. While this provides evidence of biological validity for this specific gene set, broader systematic benchmarking across larger gene panels and diverse disease contexts is needed to establish generalizability. The five-

gene demonstration serves as proof-of-concept rather than comprehensive validation across the full spectrum of human genes and regulatory relationships. Nevertheless, the framework's modular design enables application to any gene set or cancer type, with validation scope expandable based on specific research questions.

Network Scope: The current implementation supports 10 cell types derived from publicly available scRNA-seq data. Expanding to additional cell types requires access to high-performance computing resources for ARACNe network reconstruction (12-14 hours per cell type, 64-128 GB RAM). We provide documentation for advanced users to add cell types, but this remains a computational barrier for typical research labs.

Topology-Based Perturbation Analysis: Our perturbation analysis ranks regulators based on network topology (connectivity, cascade overlap) rather than predicting gene expression changes. This design choice reflects data availability—dynamic gene expression prediction requires time-series perturbation experiments currently unavailable at single-cell resolution across cell types. Topology-based ranking identifies regulators for experimental validation rather than replacing experimental perturbation studies. Experimental validation remains essential to confirm predicted regulatory relationships and quantify expression changes.

Network Construction Methodology: ARACNe networks are reconstructed from scRNA-seq data using mutual information on the top 1,024 highly variable genes. Several important limitations apply: (1) Genes with low or uniform expression across cells will not appear in networks, potentially missing important regulators with constitutive low expression; (2) ARACNe identifies correlation-based statistical associations (mutual information) rather than directional regulatory relationships—network edges represent co-expression patterns that suggest potential regulation but do not confirm regulatory directionality or direct transcription factor binding; (3) False positive rates in inferred networks depend on sample size and data quality, meaning not all identified edges represent true biological regulation; (4) The method assumes steady-state gene expression and may not capture dynamic or transient regulatory relationships. Chromatin immunoprecipitation (ChIP-seq) data could complement networks with binding-site information to confirm regulatory directionality, though such data are not yet available at single-cell resolution across diverse cell types. Users should interpret network edges as hypotheses about regulatory relationships requiring experimental validation, not as established causal mechanisms.

Pathway Enrichment Dependence: Reactome pathway enrichment requires API calls, introducing latency (1-3 seconds) and external dependency. Offline pathway databases could reduce latency but would require periodic updates to maintain currency. Current implementation prioritizes up-to-date pathway annotations over speed.

Prototype Implementation: The system is currently deployed as a local Model Context Protocol server for Claude Desktop, requiring Python installation and network cache setup. While this provides a functional conversational interface, broader accessibility would benefit from web-based deployment. However, web deployment introduces challenges of API rate limiting, compute costs for network analysis, and data privacy considerations for proprietary gene lists.

Future Directions

Several extensions could enhance RegNetAgents' capabilities while maintaining simplicity and accessibility:

Expanded Cell Type Coverage: Integration of additional cell types from CellxGene as new datasets become available. The existing preprocessing pipeline can be applied to new cell types (cardiomyocytes, neurons, hepatocytes) to broaden disease applicability without requiring new methodologies.

Additional Gene Databases: The system currently integrates UniProt protein function annotations for comprehensive gene characterization. Future integration of DrugBank for existing therapeutic information and drug-target relationships would further enrich domain agent analyses with minimal architectural changes, as DrugBank provides structured APIs similar to currently integrated resources.

Performance Optimization: Caching strategies for frequently queried genes and pathway results could further reduce latency for common use cases. Pre-computation of centrality metrics for additional cell types would eliminate first-query overhead.

Web Deployment: While currently deployed locally via Model Context Protocol, a web-based interface would improve accessibility for researchers without Python expertise. This would require consideration of API rate limiting and compute resource management but follows established patterns from existing bioinformatics web tools.

Broader Impact and Intended Use

RegNetAgents addresses a critical accessibility barrier in computational biology: the expertise gap between sophisticated analytical methods and experimental researchers who could benefit from them. By providing a conversational interface to multi-hour analytical workflows, the framework enables biologists to rapidly generate hypotheses, prioritize experiments, and explore regulatory mechanisms without programming expertise.

Intended Use: The framework is designed for hypothesis generation and experimental prioritization, not for making clinical decisions or claiming novel biological discoveries. Users should:

1. Validate hypotheses experimentally - Network predictions require experimental confirmation
2. Consult domain experts - Biological interpretations should be reviewed by specialists
3. Consider limitations - Topology-based analysis does not predict dynamic gene expression changes
4. Review literature - Framework outputs should be compared against current biological knowledge

The modular architecture—separating workflow orchestration (LangGraph) from interface (MCP server)—enables deployment across multiple contexts: command-line tools for computational biologists, REST APIs for web applications, and computational notebooks for reproducible research. This flexibility facilitates integration into existing research workflows rather than requiring adoption of entirely new platforms.

Open data principles underpin the framework: regulatory networks derive from publicly available CellxGene data (via GREMLN team preprocessing), pathway annotations use the open Reactome database, and gene annotations come from NCBI-backed resources. This ensures reproducibility and transparency of analytical methods.

CONCLUSIONS

RegNetAgents transforms labor-intensive manual gene regulatory analysis into second-scale automated workflows through multi-agent AI orchestration, making sophisticated computational methods accessible to experimental biologists. Demonstration on colorectal cancer biomarkers showed the framework can recapitulate literature-confirmed regulatory patterns and generate testable hypotheses for experimental validation. The topology-based therapeutic target prioritization ranked highly literature-supported TP53 interactors alongside novel candidates, demonstrating utility for hypothesis generation and experimental prioritization. The conversational interface via Model Context Protocol enables natural language queries without programming expertise. By integrating network analysis, network-based target ranking, pathway enrichment, and multi-domain interpretation into a unified accessible platform, RegNetAgents addresses critical bottlenecks in hypothesis generation and experimental prioritization. The modular architecture enables extension to new cell types, analysis agents, and deployment contexts. This framework is intended as a hypothesis generation tool to assist researchers, not as a replacement for experimental validation or expert biological interpretation.

ACKNOWLEDGMENTS

We thank the Chan Zuckerberg Initiative and the Califano Lab (CZ Biohub NY / Columbia University) for the GREmLN project and for preparing and publicly releasing the preprocessed ARACNe networks used in this work. We acknowledge the GREmLN development team (Zhang et al. 2025) for making these networks publicly available through the Virtual Cells Platform. We thank CellxGENE for curating and providing access to single-cell RNA-seq datasets and the Reactome team for maintaining the pathway database and API. We thank the Claude AI team at Anthropic for developing the Model Context Protocol enabling conversational interfaces.

Development Note: This project was developed with significant assistance from Claude Code (Anthropic's AI coding agent), which provided guidance on software architecture, Python implementation, workflow orchestration, documentation, and manuscript preparation. Microsoft Copilot provided valuable feedback on manuscript structure, clarity, and technical rigor during the pre-submission review process. This work demonstrates how AI-assisted development tools can enable researchers from diverse backgrounds to implement sophisticated computational frameworks, broadening participation in computational biology research.

AUTHOR CONTRIBUTIONS

J.A.B. conceived the project, designed the analysis framework, performed validation studies, and wrote the manuscript with substantial assistance from Claude Code. Software implementation, architecture, and manuscript preparation were developed collaboratively with Claude Code (Anthropic AI coding agent). This work demonstrates the potential of AI-assisted development and writing tools to enable researchers from diverse backgrounds to tackle complex computational biology challenges.

FIGURE LEGENDS

Figure 1. RegNetAgents Multi-Agent Architecture.

Workflow schematic showing the directed acyclic graph of agent execution. User queries enter through the MCP server interface and are routed to the initialization/validation agent for gene identifier resolution. The network modeling agent retrieves regulators and targets from pre-computed ARACNe networks and classifies regulatory roles. Intelligent routing determines whether therapeutic target prioritization is triggered (genes with >5 regulators). Pathway enrichment queries Reactome API for statistical validation. Four domain-specific agents (cancer biology, drug discovery, clinical relevance, systems biology) execute in parallel, each providing specialized interpretation. The integration agent synthesizes findings into a comprehensive JSON report. Dashed lines indicate conditional execution; solid lines indicate required steps.

Figure 2. Colorectal Cancer Biomarker Panel Regulatory Architecture.

(A) Network diagram showing the five analyzed genes (MYC, CTNNB1, CCND1, TP53, KRAS) with regulators (upstream arrows) and targets (downstream arrows) in the epithelial cell network. Node size represents number of connections; node color indicates regulatory role classification (red = hub regulator, orange = heavily regulated, blue = weakly regulated). TP53, MYC, and CTNNB1 emerge as central hubs with extensive downstream connectivity. (B) Bar chart comparing number of regulators (left) and targets (right) for each gene. (C) Biomarker type classification showing diagnostic, prognostic, and predictive categories.

Figure 3. TP53 Therapeutic Target Prioritization and Regulator Ranking.

(A) Network diagram showing TP53 (center) with 7 upstream regulators. All regulators contribute equal direct regulatory loss ($14.3\% = 1/7$ regulators). Node size represents downstream target count (larger = more targets = potential off-target effects). Top 3 regulators by PageRank are highlighted with color. (B) Horizontal bar chart of PageRank centrality scores for all 7 regulators, ranked from highest (WWTR1, 0.473) to lowest (IKZF2, 0.399). PageRank differentiates therapeutic potential when regulatory loss is equal. Color intensity indicates network influence. (C) Alternative ranking by degree centrality showing downstream target count, with RBPMS highest (403 targets).

Annotations indicate regulators with literature validation (WWTR1, YAP1 - Hippo pathway) vs. novel hypotheses (RBPMS).

Figure 4. Framework Value Demonstration: Workflow Automation and LLM Intelligence.

(A) Traditional manual workflow for gene regulatory analysis requires sequential querying of multiple databases (STRING/BioGRID for network data, Reactome/Enrichr for pathway enrichment, PubMed for literature curation) followed by manual synthesis, totaling 2-4 hours per gene. Workflow shown as four sequential steps with time estimates. (B) RegNetAgents automates this workflow through natural language interaction with Claude Desktop, executing parallel multi-agent analysis (network modeling, therapeutic target prioritization, pathway enrichment, four domain agents) in 0.6-15 seconds. (C) Performance comparison bar chart showing orders of magnitude speedup across single and multi-gene analyses in both rule-based and LLM-powered modes. Manual workflow baseline: 2.5 hours per gene (conservative estimate); 5-gene panel: 12.5 hours. Horizontal bars on logarithmic scale. (D) LLM-powered mode (right panel) adds scientific rationales and biological interpretations (+14 seconds) compared to rule-based network metrics and qualitative classifications only (left panel, 0.6 seconds), demonstrated with TP53 analysis. Example shows how LLM integrates gene function data (NCBI/UniProt) with network topology to provide biological context. System includes transparency flag (llm_powered: true/false) and graceful fallback to rule-based mode if Ollama unavailable.

DATA AVAILABILITY

All data and results needed to evaluate the conclusions in the paper are present in the paper and/or the figures.

Regulatory network data were obtained as pre-computed ARACNe networks prepared by the GREmLN team (Zhang et al. 2025, bioRxiv 2025.07.03.663009). These preprocessed ARACNe networks for 10 cell types are publicly available through the GREmLN Quickstart Tutorial at <https://virtualcellmodels.cziscience.com/quickstart/gremln-quickstart>.

Raw analysis outputs (JSON format) for the case study analyses presented in this manuscript are available from the corresponding author upon reasonable request.

Supplementary Material: Complete LLM prompt templates for all four domain agents, prompt engineering notes, and reproducibility instructions are provided in Supplementary Material (Table S1).

CODE AVAILABILITY

The RegNetAgents software implementation is publicly available at <https://github.com/jab57/RegNetAgents> under the MIT License.

Installation requires Python 3.8+ and takes approximately 5-10 minutes. Network data files (pre-computed ARACNe networks from GREmLN) are downloaded from the GREmLN Quickstart Tutorial as documented in the repository README. All analytical methods and workflow orchestration code are provided to facilitate independent use and extension by the research community.

Example JSON Output: The framework returns structured JSON responses. Example for TP53 analysis (abbreviated):

Data and License Information: Network data are publicly available through the GREmLN Quickstart Tutorial (<https://virtualcellmodels.cziscience.com/quickstart/gremln-quickstart>, provided by the GREmLN team under CC0 public domain dedication). Underlying single-cell RNA-seq data originate from CELLxGENE Data Portal (CC-BY-4.0 and CC0 licenses depending on dataset). Reactome pathway annotations are freely available via the Reactome API (<https://reactome.org/AnalysisService/>, Creative Commons Attribution 4.0 International License). All dependencies (NetworkX, LangGraph, pandas) are open-source with permissive licenses (BSD-3-Clause for NetworkX, MIT for LangGraph).

Network data used in this study are publicly available through the GREmLN Quickstart Tutorial (<https://virtualcellmodels.cziscience.com/quickstart/gremln-quickstart>). Pathway enrichment was performed using the publicly accessible Reactome API (<https://reactome.org/AnalysisService/>).
